band, approximately as $L_\text{r} \sim 10^{-26.8} n_3^2 T_1^{1/2} V_1 \text{erg s}^{-1}$, where $V_1$ is the effective volume of the emitting region, $\sim r_1^3$. In the preceding example $r_1 \sim 10^{10.6} \text{cm}$ and $L_\text{r} \sim 10^{32} \text{erg s}^{-1}$. The kinetic energy flux in the flow at $r_1$ is $E_A \sim 10^{35.2} \text{erg s}^{-1}$ so that the required energy can be supplied.

Such a system can naturally and simultaneously possess an optically thick, more energetic, pulsed X-ray source, derived from the ultimate accretion of the material (parallel to field lines) onto the magnetic poles of the central object.

We note that the non-steady state can also be of interest. So long as some material is being accreted from infinity it should accumulate in the throat region (held out by the waves produced by the rotating central object) until the density for steady accretion, $n_0$, is reached there. The region will then empty onto the star, and the process should repeat. This would produce periodic X-ray flaring with period $P \sim \rho c_0^2 (A_A + A_B)/\rho c_0^2 (A_A + A_B) \sim \rho c_0^2 (A_A + A_B) \sim \rho c_0^2 (A_A + A_B)$ (the magnetic accretion rate from the throat).

Using the illustrative values of $\rho$, $M$, we have $P \sim 10^4 T_1^{1/2} n_3^{1/2} \chi_0^2 (\sim 1 \text{yr for typical interstellar medium parameters}).$ The duty cycle would be roughly $A_A/A_B \sim 10^6 n_0 T_1^{3/2} n_3^{1/2}$ so that the “on-time” is just $10^8 n_0^2 \chi_0^2$. This is at most a few days in these cases (one expects really a gradual strengthening over about a year followed by a rapid decline from maximum). This mechanism may be relevant to variable galactic sources.

Such systems may already have been observed in CX-3 andHX-1 (refs. 9, 10). But the binary nature of these sources may introduce complications. We do not expect our theory to apply exactly unless the orbital velocity of the central object is less than $v_0(r_1)$. Moreover, the likely presence of gas streams in the system will present a changing supply of accretible material. It is possible that such orbiting material may permit an explanation of the observed anomalous minima if the orbit were comet-like (to pass through such a cloud in about 9 days at a speed of a few hundred km s$^{-1}$ (ref. 10) requires the cloud size (and thus the orbit size) to be $\geq 10^{13} \text{cm}$. But if this is so, one should observe the strong optically thin emission appearing and decaying before the strong pulsed emission (assuming the encounter does not always coincide with an eclipse) by a time at least of order $r_1/w (\sim 10^{-2} \text{s in the above example, and about } 10^{3} \text{s for CX-3 as discussed below}).$

Applying the theory as it stands, however, we find from the energy suggested for CX-3 ($10^{33} \text{erg s}^{-1}$ in nonpulsed emission) that $n_0 \sim 10^{14} \text{ cm}^{-3}$, $v_0 \sim 10^8 \text{ cm s}^{-1}$, $r_1 \sim 10^{13} \text{ cm}$ and $A_A/A_B \sim 10^6$. This can be achieved by having the radiated energy (in a unit solid angle). The required density of the cloud region is $n_0 \sim 10^{13} \text{ cm}^{-3}$ so that $T_1 \sim 10^{5.5} \text{ K}$. If we assume the asymptotic behaviour of $v_0$ for $r \ll r_1$, namely $v_0 \propto r_1^{1/2}$ as holding everywhere inside $r_1$, then with the above value of $v_0(r_1)$ we have $\Omega v_0 \sim 10^{10} (v_0/r_1)^{1/2}$ or $r_1 \sim 10^5 \text{ cm}$ and $2\pi/r_1 \sim 4.84 \text{ s}$, which gives $\omega \sim 2 \pi r_1/2$. This is a lower limit to $r_1$ because $v_0$ will not vary so rapidly as assumed near $r_1$, but it suggests that CX-3 is a neutron star rather than a white dwarf.

In HX-1 an pulse seems to have been observed$^{10}$. We expect these on the present model because of the probable thermal origin of the pulsed emission. If we assume a simple geometry, then the inclination between the rotation and magnetic axis is $\chi = \pi/2 - (\theta_1 + \theta_2)/2$, where $\theta_1, \theta_2$ are the angles made by the line of sight to the two magnetic poles ($\theta_1$ is the smaller; that is, refers to brighter pole). If we assume that the observed intensity ratio$^{10}$ (pulse-interpulse) of about 2 is simply a projection effect (cosine ratio), and for $\theta_2$, within $20^\circ$ of $0^\circ$, $\theta_2 = 60^\circ$ and $\chi = 50^\circ - 60^\circ$. To make the intensity ratio at least to 1 as may be true for CX-3 we find $\chi = 38^\circ - 48^\circ$ for $\theta_2$ within $20^\circ$ of $0^\circ$.

The numbers given here are primarily qualitative; but it is intriguing to observe how closely this new picture has duplicated the numerical results of Prendergast and Burbidge$^{11}$, who worked from the observed properties of SX-1 and CX-2 but also allowed for the effects of angular momentum.

**Rigidity Spectrum of Helium Nuclei above 17 GeV and a Search for High Energy Anti-nuclei in Primary Cosmic Rays**

We present here some results obtained with a magnet spectrograph flown from Hyderabad (geomagnetic cutoff $\sim 17$ GeV) in May 1970. The two principal results are: there is no anomaly in the differential spectrum of helium nuclei close to the geomagnetic cutoff; and no anti-nuclei have been seen up to a rigidity of $\sim 100$ GeV.

The instrument has been described earlier$^3$. It consists basically of three glass plates covered with emulsion for accurate coordinate measurement, a $2 \text{ kg}$ permanent magnet for particle bending, two wide gap spark chambers for trajectory location and a suitable triggering system. A total of 116 nuclei (mostly helium and some heavier) have been followed from spark chambers to the nearest emulsion plate and subsequently to other plates. The procedures for track-following and other questions, such as the errors involved, are discussed elsewhere$^2$.

The coordinates of the tracks in the three plates were measured to an accuracy of $\sim 1 \mu$. The surfaces of the glass plates were optically worked and calibrated such that their profile was known to an accuracy of $\sim 2 \mu$. The total error in the determination of the sagitta of the trajectory in the middle plate was $\sim 3 \mu$. Mean sagitta of a $15$ GeV particle being $45 \mu$, the maximum detectable rigidity was $\sim 220$ GeV. The error due to multiple Coulomb scattering (chiefly in the central plate) was $\sim 27\%$.

A common coordinate frame for the three plates can be obtained by demanding the linearity of field-free tracks. Because these were not available, we had to devise a procedure for using the tracks passing through the magnetic aperture, making use of the fact that these tracks differ from the field-free tracks only through a bending in a well defined direction. Measurements of these tracks, then, yield a deflection distribution whose zero is shifted from that of the true distribution by an unknown amount. By changing the zero offset of this distribution one obtains varying rigidity distributions. But if
of Pinkau et al. and Grigorov et al. have been converted into differential points. The measurements shown in the figure have been made by one of the two techniques: magnetic bending or ionization calorimetry. The two sets of measurement agree with each other rather well in the overlapping region. The spectrum is quite smooth up to the highest energy of ~2,000 GV and consistent with a slope of -2.7.

Fig. 2 Differential rigidity spectrum of the helium nuclei for rigidity higher than 10 GV as measured in various experiments. Data points for measurements of Pinkau et al. and Grigorov et al. have been derived from the integral values given by them. Anand et al. (geometric effect); ◇, Buffington et al. (magnet spectrograph); □, present experiment (magnet spectrograph); ○, Ryan et al. (calorimeter); △, Grigorov et al. (calorimeter); +++, Pinkau et al. (calorimeter).

Fig. 3 Inverse-rigidity distribution for all the measured tracks. It is seen that there is no negative value beyond -0.01 (GV)^{-1}. The experimental error is about 0.005 (GV)^{-1}.

Because in this experiment we measure the deflexion of particles in a magnetic field we would directly see anti-nuclei if they were present. In Fig. 3 we have plotted the measured 1/R spectrum for the exponent of the rigidity spectrum -2.8. The total measurement error is about 0.005 (GV)^{-1}. There are

no particles on the negative side beyond $-0.01$ (GV)$^{-1}$. In the absence of anti-nuclei the number of particles expected on the negative side caused by Coulomb scattering is $\sim 0.3$. Thus we can put an upper limit to the flux of anti-helium nuclei as $\sim 1\%$ of the flux of helium nuclei in the rigidity range of 14–100 GV. If we split the total rigidity range into the bins of 14–30, 30–50, and 50–100 GV, the corresponding upper limits are 2%, 2%, and 10%. So far no anti-nuclei have been found in primary cosmic rays and only upper limits exist. Our upper limits, together with those obtained by others, are given in Table 1.

Cretaceous Deep-sea Manganese Nodules on Timor: Implications for Tectonics and Olistostrome Development

PROBABLY the best known occurrence of fossil manganese nodules closely resembling deep-sea nodules of modern oceans are those of western Timor$^1$. They occur with micronodules in a red clay similar to recent deep-sea red clays$^2$. Their chemistry and physical characters provide the basis for thinking that these nodules, micronodules and the red clay matrix were originally deposited on the deep-sea floor of a Cretaceous ocean$^3$$^4$. Two questions arise: How did this portion of ocean...

Fig. 1. Location of the Cretaceous ferromanganeseiferous deposits near Niki Niki and Wai Bua, and the Middle Eocene deposits at Seical.

Fig. 2. Reconstruction of the Outer Banda Arc in the Middle Miocene$^5$ showing the known and inferred emplacement of the Bobonaro Scaly Clay olistostrome. The present distribution of the olistostrome seems to be closely related to the occurrence of overthrust sheets of the Permian Mauvisse Formation. The presence of the olistostrome in Kai and Seram is interpreted from reports of mud volcanoes and landslides forming a "soup of shales and limestone blocks"$^{16}$. Its presence below the Timor Trough seems very likely in view of its tendency to thicken southwards in southern Timor, which implies the declivity down which it slid continued southwards towards the Miocene Timor Trough$^{16}$.
