ABSTRACT

We present the discovery and validation of a three-planet system orbiting the nearby (31.1 pc) M2 dwarf star TOI-700 (TIC 150428135). TOI-700 lies in the TESS continuous viewing zone in the Southern Ecliptic Hemisphere; observations spanning 11 sectors reveal three planets with radii ranging from 1 R_{\oplus} to 2.6 R_{\oplus} and orbital periods ranging from 9.98 to 37.43 days. Ground-based follow-up combined with diagnostic vetting and validation tests enable us to rule out common astrophysical false-positive scenarios and validate the system of planets. The outermost planet, TOI-700 d, has a radius of $1.19 \pm 0.11 R_{\oplus}$ and resides in the conservative habitable zone of its host star, where it receives a flux from its star that is approximately 86% of the Earth's insolation. In contrast to some other low-mass stars that host Earth-sized planets in their habitable zones, TOI-700 exhibits low levels of stellar activity, presenting a valuable opportunity to study potentially-rocky planets over a wide range of conditions affecting atmospheric escape. While atmospheric characterization of TOI-700 d with the James Webb Space Telescope (JWST) will be challenging, the larger sub-Neptune, TOI-700 c ($R = 2.63 R_{\oplus}$), will be an excellent target for JWST and beyond. TESS is scheduled to return to the Southern Hemisphere and observe TOI-700 for an additional 11 sectors in its extended mission, which should provide further constraints on the known planet parameters and searches for additional planets and transit timing variations in the system.

Keywords: Exoplanet systems — Transit photometry — Low mass stars — M dwarf stars — Astronomy data analysis

1. INTRODUCTION

The search for small, rocky planets like Earth orbiting stars outside of our solar system has made rapid progress in the last decade. The *Kepler* mission (Borucki et al. 2010), launched in 2009, was designed to explore a specific exoplanet population, Earth-sized planets in Earth-like orbits around Sun-like stars, and aimed to address how common they are. *Kepler* achieved a number of significant milestones towards this quest, including finding planets within their host stars' habitable zones. The habitable zone is the region around a star where liquid water could be stable on the surface of a planet if it has an atmosphere with the appropriate properties (Shapley 1953; Strughold 1953). Kepler-22 b marked the first small planet found within the habitable zone of its host star (Borucki et al. 2012). But with a radius $> 2 R_{\oplus}$, it is unlikely that Kepler-22 b is rocky (Rogers 2015). The Kepler-62 system has two small planets receiving Earth-like insulations from their early-K host star (Borucki et al. 2013, 2019), but these planets orbit a relatively distant (~ 300 pc), faint star that makes follow-up challenging.

Among the most important discoveries by *Kepler* was the high frequency of planets orbiting low-mass M dwarfs (Dressing & Charbonneau 2013, 2015; Gaidos et al. 2016; Hardegree-Ullman et al. 2019), particularly small ($< 2 R_{\oplus}$) planets in compact multiplanet systems. The first definitively Earth-sized planet discovered in the habitable zone of its host star, Kepler-186 f (distance = ~ 179 pc), resides in a multiplanet system orbiting an M dwarf about half the mass of the Sun (Quintana et al. 2014; Torres et al. 2015).

Kepler's extended mission, *K2*, surveyed substantially more sky than the prime mission and collected data for an order of magnitude more M dwarfs than were observed in *Kepler's* prime mission (~ 3000 M dwarfs in the prime mission, Huber et al. 2016). *K2's* focus on low-mass stars led to the discovery of hundreds of small transiting planets, among them habitable zone planets orbiting bright stars such K2-3 d (Crossfield et al. 2015), K2-18 b (Montet et al. 2015; Benneke et al. 2017), K2-9 b (Montet et al. 2015; Schlieder et al. 2016), K2-72 e (Dressing et al. 2017), and K2-288B b (Feinstein et al. 2019). Of these planets, only K2-72 e with $R = 1.3 R_{\oplus}$ has a radius that is small enough to potentially be rocky (Rogers 2015). Despite the large number of small planet discoveries, due to the design of the *Kepler* and *K2* target selection and their limited mission durations, the majority of targets in question are too dim for detailed follow-up observations.

The relative ease of finding small planets orbiting M dwarfs, compared with Sun-like stars, has made them

prime targets for exoplanet hunters using both transit photometry and ground-based radial velocity facilities. Radial velocity searches for planets orbiting low-mass stars pre-date *Kepler* (Plavchan 2006; Bonfils et al. 2013), and have led to discoveries of low-mass planets in the habitable zone (Anglada-Escudé et al. 2013, 2016). Both ground-based radial velocity and transit photometry surveys searching nearby and bright M dwarfs have discovered systems of planets with the potential for detailed follow-up. These systems include GJ 1214 b (Charbonneau et al. 2009), GJ 1132 b (Berta-Thompson et al. 2015), and LHS 1140 b and c (Dittmann et al. 2017; Ment et al. 2019) from the MEarth program (Nutzman & Charbonneau 2008), Proxima Centauri b (Anglada-Escudé et al. 2016), and the seven approximately Earth-sized planets transiting the very late-M dwarf TRAPPIST-1 (Gillon et al. 2017; Luger et al. 2017). LHS 1140 b is a particularly compelling target, as it is a transiting super-Earth in the habitable zone with a radial velocity-measured mass that indicates a rocky composition (Ment et al. 2019). Additionally, the planets in the TRAPPIST-1 system that reside in the star's habitable zone have a range of masses (determined via transit timing variations) suggesting compositions from rocky terrestrials to more volatile-rich Earth-size planets (Grimm et al. 2018; Dorn et al. 2018).

The Transiting Exoplanet Survey Satellite (TESS, Ricker et al. 2015), launched in April 2018, is performing a near-all-sky photometric survey designed to search for small planets around the Sun's nearest neighbors – those bright enough for follow-up characterization. The TESS photometric bandpass is redder than *Kepler's* which facilitates higher sensitivity to planets orbiting cooler, low-mass stars (Sullivan et al. 2015; Ricker et al. 2015; Barclay et al. 2018; Ballard 2019). TESS is now well into its second year of operations and it is delivering on its promise to identify small planets around the closest, brightest M dwarfs. To date, 11 small planets have been discovered orbiting M dwarfs with K_s -band magnitudes of 6–11. Among these are four compact multiplanet systems: TOI-270 b, c, and d (Günther et al. 2019), L 98-59 b, c, and d (Kostov et al. 2019b), GJ 357 b and c (Luque et al. 2019), and LP 791-18 b and c (Crossfield et al. 2019). TOI-270 d is a sub-Neptune in the habitable zone of its host star, potentially similar to K2-18 b. As each of the TESS-discovered systems is a new potential benchmark, intensive follow-up is ongoing (Cloutier et al. 2019), and several planets have been in-

cluded as targets in Guaranteed Time Observing (GTO) programs for JWST.¹

Building on these early discoveries from TESS, here we present the discovery and validation of a system of three small planets transiting the nearby (31.1 pc), bright ($K = 8.6$ mag), M2 dwarf TOI-700. This system includes a nearly Earth-sized planet in the habitable zone (TOI-700 d). This paper is the first in a series of three papers. In this paper we describe the TESS observations of the system (Section 2), derive precise stellar properties of the host star (Section 3), model planet parameters (Section 4), discuss the observational constraints and our vetting and validation of the system (Section 5), and explore the dynamics of the system (Section 6). In Paper II, Rodriguez et al. (submitted) use *Spitzer* observations to provide independent confirmation that TOI-700 d is a transiting planet and refine its parameters, and in Paper III, Suissa et al. (submitted) simulate potential climate configurations for TOI-700 d to explore the prospects of both habitable conditions and atmosphere detection.

2. TESS OBSERVATIONS

TOI-700 (TIC 150428135, 2MASS J06282325-6534456, UCAC4 123-010026) was prioritized for inclusion in the TESS 2-minute cadence mode target list because it was included as a target in the TESS Guest Investigator Program Cycle 1 proposal G011180 - *Differential Planet Occurrence Rates for Cool Dwarfs* (P. C. Dressing).² TOI-700 is only 3° away from the South Ecliptic Pole, as shown in Figure 1. This resulted in TOI-700 falling into the field of view of TESS Camera 4 in 11 of the 13 observing sectors that made up the first year of TESS science (sectors 1, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 13), spanning 25 July 2018 to 18 July 2019. During the remaining two sectors, TOI-700 fell into gaps between detectors.

The TESS Science Processing Operation Center (SPOC) pipeline (Jenkins et al. 2016) first identified two planet candidates transiting TOI-700 in June 2018 in a search of combined photometry from the first 5 sectors where it was observed. A third planet candidate was identified by the pipeline in August 2019 in the combined data from the first 8 sectors where it was observed. These candidate planets had short periods of 9.98 (TOI-700.03), 16.05 (TOI-700.01), and 37.42 (TOI-700.02) days, transit depths ranging from 600–

3000 ppm, and signal-to-noise ratios of 9.8, 27.4, and 10.0. The pipeline-estimated planet radii were consistent with sub-Neptunes to sub-Saturns, but this was due to missing stellar parameters in the version of the TESS Input Catalog (TIC, Stassun et al. 2018, 2019) used at the time (TIC V6) and $1 R_\odot$ being adopted by default. We noted that TOI-700 was included in GI proposal G011180, a cool dwarf survey, raising red flags about the $1 R_\odot$ stellar radius. We then used its broad-band photometric colors (see Table 1) to estimate that it was likely an M2–M4 dwarf with a radius in the range of $0.25\text{--}0.5 R_\odot$. With these revised stellar properties, the observed transit depths indicated the planets were small, with radii spanning approximately $1\text{--}3 R_\oplus$. This early indication of a compact system of small planets transiting a bright M dwarf led to a deeper investigation of the host star, and subsequently, the planet candidates.

3. DETERMINING THE PROPERTIES OF TOI-700

Understanding the host stars is an essential component of validating and characterizing exoplanets. Here we use both empirically-derived relations based on the absolute magnitudes (see Section 3.1) and spectral energy distribution (SED) based models (see Section 3.2) to estimate the star’s fundamental parameters. We compared three different methods and showed they provided consistent results. We also estimated stellar parameters using an observed medium resolution spectrum and again derived consistent results.

3.1. Empirically Derived Stellar Parameters

We determined fundamental parameters of TOI-700 using empirical relations for M dwarfs that are based on the variation of mass, radius, luminosity, and temperature with absolute 2MASS K_s -band magnitude (M_{K_s}). This approach is similar to the methods used in other recent TESS discoveries of small planets transiting M dwarfs (e.g. L 98-59 and LTT 1445A, Kostov et al. 2019b; Winters et al. 2019b). Specifically, we used the M_{K_s} -mass relation of Mann et al. (2019),³ calibrated using M dwarf binaries with precise orbit fits and mass determinations, to estimate the mass of TOI-700. We then used the M_{K_s} -radius relationship of Mann et al. (2015), calibrated using M dwarfs with interferometrically measured radii, to estimate the stellar radius. To calculate the effective temperature (T_{eff}), we estimated the K -band bolometric correction using the relations of Mann et al. (2015) to calculate the stellar luminosity and then combined it with the measured radius estimate using

¹ L 98-59 c and d - NIRISS and NIRCams programs, GJ 357 b - NIRISS program, LP 791-18 c - NIRISS program

³ <https://github.com/awmann/M.-M.K->

Figure 1. TOI-700 is close to the South Ecliptic Pole and was observed by TESS in 11 of the first 13 sectors of the mission. The field around TOI-700 is relatively uncontaminated, with approximately 1% of the starlight in the region around TOI-700 coming from other stars. The blue dashed line in the figure is the TESS Continuous Viewing Zone (CVZ). The blue square in the upper-left inset shows TOI-700.

the Stefan-Boltzmann law. The derived parameter estimates are consistent with an $M2V \pm 1$ dwarf following the color-temperature relations of [Pecaut & Mamajek \(2013\)](#).⁴ We estimated parameter uncertainties using Monte Carlo methods assuming Gaussian distributed measurement errors and add the systematic scatter in the parameter relations in quadrature. We find the stellar radius is $0.420 \pm 0.031 R_{\odot}$, mass is $0.416 \pm 0.010 M_{\odot}$, effective temperature is 3480 ± 135 K, and mean stellar density is $8.0 \pm 1.8 \text{ g cm}^{-3}$.

⁴ We used the updated stellar parameter table, Version 2019.3.22, available at http://www.pas.rochester.edu/~emamajek/EEM_dwarf_UBVIJHK_colors_Teff.txt

We also used the star’s photometry to estimate its metallicity via its position on a color-magnitude diagram. Color-magnitude position is mainly sensitive to $[\text{Fe}/\text{H}]$ for single M dwarfs, unlike for Sun-like stars where color-magnitude diagram position also depends on age (due to main sequence evolution). We interpolated over five different metal-sensitive color-magnitude combinations (using *Gaia*, 2MASS, and APASS photometry) using stars with accurate metallicities from near-infrared spectra ([Rojas-Ayala et al. 2012](#); [Mann et al. 2013](#); [Newton et al. 2014](#)) and parallaxes from *Gaia* DR2. This method yielded a consistent metallicity across all relations, with a final adopted value of $[\text{Fe}/\text{H}] = -0.07 \pm 0.11$, and errors limited primarily by the $[\text{Fe}/\text{H}]$ values applied to the comparison sample.

These stellar properties are adopted as the set we use in the analyses presented in the rest of the paper. They are summarized in Table 1, along with the star’s astrometric and photometric properties. In the following sub-sections we use additional methods and data to validate these parameters.

3.2. Validation of the Stellar Parameters with Alternative SED Models

We used two additional SED-based methods to derive stellar parameters to validate the previous analysis. The first check employed the methods and procedures described in Kostov et al. (2019b) and combined the stellar SED with the *Gaia* DR2 parallax to determine an empirical measurement of the stellar radius. We used the $B_T V_T$ magnitudes from *Tycho-2*, the $BVgri$ magnitudes from APASS, the JHK_S magnitudes from 2MASS, the W1–W4 magnitudes from *WISE*, the G magnitude from *Gaia*, and the NUV magnitude from *GALEX*. Together, the available photometry spans the full stellar SED over the wavelength range 0.2–22 μm .

We performed a fit using NextGen stellar atmosphere models, with the priors on effective temperature (T_{eff}), surface gravity ($\log g$), and metallicity ([Fe/H]) from the values provided in the TIC (Stassun et al. 2019). The remaining free parameter is the extinction (A_V), which we set to zero because of the star’s proximity. Integrating the model SED gives the bolometric flux at Earth, $F_{\text{bol}} = 7.15 \pm 0.34 \times 10^{-10}$ erg s cm⁻². Taking the F_{bol} and T_{eff} together with the *Gaia* DR2 parallax⁵ provides a stellar radius $R = 0.404 \pm 0.023 R_{\odot}$. Finally, estimating the stellar mass from the empirical relations of Torres et al. (2010), assuming solar metallicity, gives $M = 0.44 \pm 0.03 M_{\odot}$, which when combined with the radius results in a mean stellar density $\rho = 9.52 \pm 0.12$ g cm⁻³. These results are consistent with those from the empirically driven parameter analysis.

As a second independent check on the stellar parameters, we employ the SED fitting method of Silverstein et al. (in preparation), which is based upon the method described by Dieterich et al. (2014). In this analysis, we compared the star’s Johnson V (V_J), Kron-Cousins RI ($R_{KC}I_{KC}$), 2MASS JHK_s , and *WISE* AllWISE Release W1W2W3 to those extracted from the BT-Settl 2011 photospheric model spectra (Allard et al. 2011). We obtained $V_J R_{KC} I_{KC}$ photometry observations at the SMARTS/CTIO 0.9 m telescope in Chile on 2019 August 20 UT using the 2048×2048 Tektronix CCD camera. Following standard RECONS SMARTS/CTIO 0.9m photometry procedures (Jao et al. 2003, 2005; Winters et al. 2011), we took observations, reduced the data, and performed aperture photometry. We found nine photometric colors to be effective probes of temperature for early M dwarfs (Silverstein et al., in preparation) and compared these to colors extracted from the

⁵ Adjusted by +0.08 mas to account for the systematic offset reported by Stassun & Torres (2018).

BT-Settl 2011 model photospheres. Each color yielded a best-matching spectrum and corresponding effective temperature. The resulting value, $T_{\text{eff}} = 3480 \pm 50$ K, is the mean of these temperatures. We estimated the temperature uncertainty by adding their standard deviation in quadrature with a systematic error based on the discrete nature of the model grid. Then we calculated the flux within the full wavelength range of our filters using an iterative procedure that scaled a 3500 K model spectrum, the closest grid point to our results, until all model magnitudes were within 0.03 mag of their observed counterparts. Next, we integrated the scaled spectrum within the wavelength range of the V_J to $W3$ photometry, and we performed a correction to bolometric flux by calculating the flux that would be missing from a blackbody of the same effective temperature. We calculated the bolometric luminosity, $L_{\text{bol}} = 0.0235 \pm 0.0004 L_{\odot}$, by scaling the resultant bolometric flux, $F_{\text{bol}} = 7.73 \pm 0.12 \times 10^{-10}$ erg s cm $^{-2}$, by the inverse square of the *Gaia* DR2 parallax. We then derived a radius of $R = 0.421 \pm 0.025 R_{\odot}$ using the Stefan-Boltzmann law. We also calculated the mass of the star using the [Benedict et al. \(2016\)](#) absolute V - and K -band mass-luminosity relations for main sequence M dwarfs. We determined the weighted mean of the masses from each relation and found $M = 0.42 \pm 0.02 M_{\odot}$. These parameters are consistent with those estimated previously in this subsection.

3.3. Validation of the Stellar Parameters Using Medium Resolution Spectroscopy

We obtained a spectrum of TOI-700 with the Goodman High-Throughput Spectrograph ([Clemens et al. 2004](#)) on the Southern Astrophysical Research (SOAR) 4.1 m telescope located at Cerro Pachón, Chile. On 2019 September 30 UT and under clear (photometric) conditions, we obtained five spectra of TOI-700, each with an exposure time of 120 seconds. We took all exposures using the red camera, 1200 l/mm grating in the M5 setup, and the 0.46'' slit rotated to the parallactic angle, which yielded a resolution of $\simeq 5900$ spanning 625–750 nm. For wavelength calibration, we obtained observations of Ne arc lamps taken just before the target, as well as dome flats and biases taken during the afternoon.

We performed bias subtraction, flat fielding, optimal extraction of the target spectrum, and mapping pixels to wavelengths using a 4th-order polynomial derived from the Ne lamp data. We then stacked the five extracted spectra using the robust weighted mean (for outlier removal). The stacked spectrum had a signal-to-noise ratio > 100 over the full wavelength range (excluding areas of strong telluric contamination). While we observed

no spectrophotometric standards during the night, we corrected instrument throughput with wavelength using standards from an earlier night. The final spectrum is shown in Figure 2 compared to M2 and M3 template spectra from [Cushing et al. \(2005\)](#).

Figure 2. SOAR Goodman spectrum of TOI-700 (black) compared to an M2 (red) and M3 (blue) template spectrum. The spectrum exhibits a continuum shape and broad TiO absorption bands that are characteristic of M dwarfs. The good visual match to the M2 and M3 templates is consistent with the $M2 \pm 1$ spectral type estimated from the empirically derived effective temperature in Section 2. Because we used an archive calibration, the flux calibration of our Goodman spectrum is likely only accurate to $\simeq 10\%$.

To estimate stellar parameters using this spectrum, we constructed and fit an SED using available photometry, the spectrum, and M dwarf templates from [Gaidos et al. \(2014\)](#). More details of our method can be found in [Mann et al. \(2015\)](#), which we summarize here. We first downloaded literature optical and NIR photometry from the 2MASS ([Skrutskie et al. 2006](#)), the Wide-field Infrared Survey Explorer (WISE, [Wright et al. 2010](#)), *Gaia* data release 2 (DR2, [Evans et al. 2018](#); [Lindgren et al. 2018](#)), and AAVSO All-Sky Photometric Survey (APASS, [Henden et al. 2012](#)). We compared this photometry to synthetic magnitudes computed from the combination of our SOAR spectrum, a grid of template M dwarf spectra, and PHOENIX BT-Settl models ([Allard et al. 2011](#)) to cover gaps in the spectra. The Goodman spectrum was not as precisely flux-calibrated as the data used in [Mann et al. \(2015\)](#), so we included two additional free parameters to fit out wavelength-dependent flux variations (so the major constraint comes from the molecular band shape and depth). This joint fitting procedure yielded a T_{eff} of 3460 ± 65 K and a L_* of

$0.0236 \pm 0.0005 L_{\odot}$. Using the Stefan-Boltzmann Law, this yields a radius value consistent at $< 1\sigma$ with the value derived from the $M_{K_S} - R_*$ relation described previously. The final calibrated and combined spectrum along with archival and synthetic photometry is shown in Figure 3.

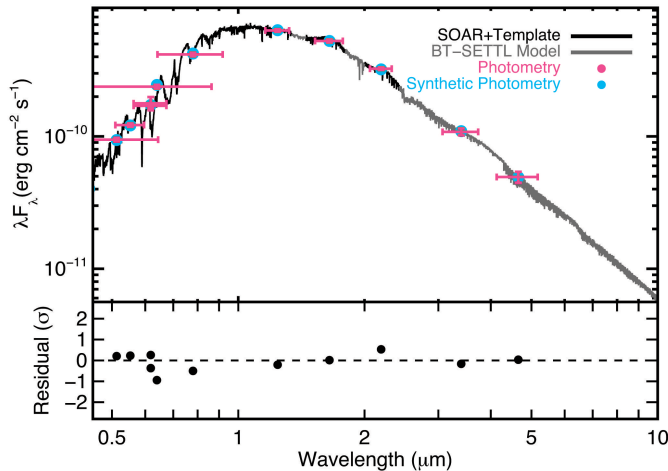

Figure 3. Best-fit spectral template and Goodman spectrum (black) compared to the photometry of TOI-700. Gray regions are BT-Settl models, used to fill in gaps or regions of high telluric contamination. Literature photometry is shown in pink, with horizontal errors corresponding to the filter width and vertical errors the measurement errors. Corresponding synthetic photometry is shown as blue points. The bottom panel shows the residuals in terms of standard deviations from the fit.

3.4. Constraints on the Age of TOI-700

Our stellar parameter analyses indicate that TOI-700 is a main sequence M2 dwarf star. M dwarfs change little over the vast majority of their very long lifespans on the main sequence, therefore precise age determinations for such stars are notoriously difficult (e.g. Newton et al. 2016; Veyette & Muirhead 2018). Early M dwarfs, like TOI-700, have magnetic dynamos similar to the Sun, and shed angular momentum over time via magnetic braking as the stellar wind interacts with magnetic field lines. This braking results in progressively slower rotation and lower levels of magnetic activity. Stellar magnetic activity manifests in the form of star spots, flares, increased X-ray and UV emission, and emission in activity-sensitive spectral lines (e.g. $H\alpha$, Na I, Ca II), which can provide additional constraints on the age of an M dwarf. In 11 sectors of TESS 2-minute cadence high precision photometry of TOI-700, there are no detectable white-light flares. Additionally, we observed no

emission in activity sensitive lines in a high-resolution spectrum (see Section 5.1.3). We also searched for excess UV emission from TOI-700 in the GALEX (Morrissey et al. 2005) catalog of Bianchi et al. (2011). There is a weak near-UV source near the location of the star but it is flagged as an image artifact so we do not attribute this detection to TOI-700.

We estimated the rotation period of TOI-700 from more than five years of archival photometry from the All-Sky Automated Survey for Supernovae (ASAS-SN) (Shappee et al. 2014; Kochanek et al. 2017). We obtained ASAS-SN data from the publicly available Sky Patrol database.⁶ The database contained TOI-700 over 2500 photometric observations in two bands, V and g , spanning approximately five years. Both the V - and g -band long baseline light curves exhibited slowly varying sinusoidal modulation, consistent with periodic brightness variations due to star spots in the photosphere of a rotating star.

We used *exoplanet* (Foreman-Mackey 2018) to model the variability in the ASAS-SN data using a periodic Gaussian process kernel (Foreman-Mackey et al. 2017; Foreman-Mackey 2018). The particular form of the periodic kernel has two peaks in frequency space: one at the model period and another at half the model period. This kernel is well suited to modeling the signature of stellar rotation (spots coming in and out of view as the star rotates) which often produces two peaks in frequency space owing to multiple spot clusters on the stellar surface. The parameters of the model were the log period, and for each of the two separate data sets the photometric mean, a log amplitude, a log quality factor of the primary frequency, a ratio of the log quality factors between the primary and secondary frequency, a ratio between the amplitude of primary and secondary frequencies, and a log noise parameter that is added in quadrature with the reported uncertainty in the data. All log parameters here are natural logarithms. In addition, for only the V -band ASAS-SN data, we included a long term variability term because there appear to be slow changes in the measured brightness of the target in that data. We sampled from this model using the PyMC3 (Salvatier et al. 2016) implementation of the No U-turn Sampler (NUTS, Hoffman & Gelman 2014) which is a form of Hamiltonian Monte Carlo. We measured the posterior rotation period to be 54.0 ± 0.8 days. Posterior draws from the model in data space are shown in Figure 4, along with posteriors for the rotation period and the multi-band amplitudes. This rotation period

⁶ <https://asas-sn.osu.edu>

is typical for inactive early-mid spectral type M dwarfs (Newton et al. 2017). The modeled amplitude of the rotation signal in the V -band is $0.6 \pm 0.1\%$ and $0.4 \pm 0.1\%$ in the g -band.

Long-baseline photometry of TOI-700 was also obtained using the HATSouth telescope network (Bakos et al. 2013) from 15 Feb 2017 through 9 May 2017. A total of 1137 r' -band exposures of 4 minute duration were obtained containing TOI 700 as a point source. The median FWHM of the point-spread-function was $7''$ at the location of TOI-700. The observations were reduced to an ensemble-corrected light curve via aperture photometry following the method described by (Penev et al. 2013). The light curve shows a clear quasi-sinusoidal variation that phases up at a period of 53.1 ± 1.2 days and a peak-to-peak amplitude of 12.6 ± 0.7 ppt. If this is the rotation period of the star, the observations span 1.6 cycles. After fitting and subtracting a sinusoid model from the light curve, we find that the residuals have a point-to-point r.m.s. scatter of 6.4 ppt. The sinusoidal variation persists after applying the standard de-trending techniques used by HATSouth, indicating an astrophysical origin. The scatter in the HATSouth light curve is too large to permit detection of any of the three transiting planet signals identified by TESS, and the time-coverage is such that no transit events were observed for TOI-700.01 or TOI 700.03. The observations do cover a predicted transit for TOI 700.02, though the transit is too shallow to be detected. While no obvious flare events are seen in the HATSouth light curve we do find a slight imbalance between the number of bright outliers in the light curve compared to faint outliers, with six total 3σ bright outliers and two 3σ faint outliers. These HATSouth observations are consistent with those from ASAS-SN and confirm the estimated rotation period of TOI-700.

Stellar galactic kinematics can be combined with the measured rotation period and activity constraints to provide additional age constraints. To calculate the galactic UVW velocities, we followed the prescription of Johnson & Soderblom (1987), updated to epoch J2000. We also adopted a coordinate system where U is positive toward the Galactic center and calculated the UVW velocities corrected to the local standard of rest (LSR, Coşkunoğlu et al. 2011). We used the available astrometry from *Gaia* DR2 and the radial velocity measurement from the CHIRON spectrum presented in this paper (see Section 5.1.3) to calculate $(UVW_{LSR}) = (-17.83, 20.34, -2.40) \pm (0.29, 0.44, 0.26) \text{ km s}^{-1}$, which yield a total Galactic velocity $S_{LSR} = 27.15 \text{ km s}^{-1}$ indicating that the star is a likely member of the thin disk population following the kinematic criteria of Bensby et al.

(2010). The typical metallicity of stars in the thin disk, $-0.7 < [\text{Fe}/\text{H}] < +0.5$ dex (Bensby et al. 2014), is also consistent with the metallicity of TOI-700 estimated in this work. Following the systematic study of M dwarf rotation and kinematics from Newton et al. (2014), the combined Galactic kinematics and rotation period indicate that TOI-700 is older than ~ 2 Gyr.

As a final check, we used *stardate* (Angus et al. 2019a,b) to estimate the age of TOI-700 using the photometry listed in Table 1, the *Gaia* parallax, and the rotation rate from ASAS-SN. This method has been calibrated and tested on stars with *Gaia* $B_P - R_P < 2.7$, so is appropriate for TOI-700. The resulting age estimate was > 1.5 Gyr at 95% confidence. This result is consistent with the above limit and is adopted as the stellar age in reported in Table 1.

4. MEASURING THE PHYSICAL PROPERTIES OF THE PLANETS ORBITING TOI-700

We determined the physical properties of the TOI-700 planets by combining the stellar properties measured previously with an analysis of the TESS time series data. Our TESS data analysis made use of the SPOC-created systematics-corrected light curves from the TESS pipeline (Jenkins et al. 2016; Smith et al. 2012; Stumpe et al. 2014) collected at 2-minute cadence. We first used the *lightkurve* package to download the datasets from the MAST archive (Lightkurve Collaboration et al. 2018) and used the *exoplanet* toolkit to create models of the light curves (Foreman-Mackey 2018) and infer the planet properties. Each of the 11 separate sectors of data have different noise properties, so we opted to model these as independent datasets with distinct noise terms. The complete light curve is shown in Figure 5. Each sector is modeled with a mean offset, a white noise term parameterized as the natural log variance, and two hyper-parameters, $\ln(S_0)$ and $\ln(\omega_0)$, of a Gaussian Process (GP) that describes a stochastically-driven, damped harmonic oscillator and models residual stellar variability. In addition to the sector-dependent parameters, the model includes two stellar limb darkening parameters, the natural logarithm of stellar density, the stellar radius, and for each planet a natural log orbital period, a natural log planet-to-star radius ratio, impact parameter, eccentricity, periastron angle, and time of first transit.

We used a Normal prior for the stellar radius with mean and standard deviation of 0.42 and 0.03, respectively, in solar units. The natural log mean stellar density, in cgs units, had a Gaussian prior with a mean of $\ln 8.0$ and standard deviation of 0.3 dex (as per Section 2.1). The limb darkening parameters were estimated

Figure 4. Long-term monitoring of TOI-700 by ground-based ASAS-SN telescopes reveal a 54.0 ± 0.8 day rotation period. The combined V -band data in blue and g -band data in green covers five years. The g -band data has been offset by -0.1. 50 posterior draws from a periodic GP kernel model are shown in purple (V -band) and pink (g -band). The lack of stellar activity and slow rotation period indicate that the star is not young. The posterior distribution of the rotation period and amplitude of the rotation signal are provided. The amplitude of the rotation is 0.6% in the V -band and 0.4% in the g -band.

Figure 5. The full 11 sector TESS light curve of TOI-700. Each sector of data is shown with a separate color. Transits of the planets are marked in blue (TOI-700 b), pink (TOI-700 c), and purple (TOI-700 d). TESS observed 25 transits of planet b, 14 transits of planet c, and 8 transits of planet d. Transits that occur during gaps in the TESS data collection do not have a dot below the transit model.

following Kipping (2013a) and were sampled uniformly. The impact parameter was uniformly sampled between zero and one plus the planet-to-star radius ratio. The eccentricity had a beta prior (as suggested by Kipping 2013b), with parameters appropriate for systems of small planets (Van Eylen et al. 2019) and was bounded between zero and one. The periastron angle at transit was sampled from an isotropic two-dimensional normal with the angle given by the arctangent of the ratio of the two coordinates, yielding uniform prior between $-\pi$ and π with no hard boundaries (Foreman-Mackey 2018).

We used the PyMC3 to make draws from the posterior distribution. We used 4 independent chains and ran 6000 tuning steps and then 5000 draws which we used for inference. The chains were well mixed and the number of effective samples was over 1000 for each model parameter. The Gelman–Rubin diagnostic (Gelman & Rubin 1992) measures convergence between independent chains. All model parameters had a Gelman–Rubin diagnostic within one part in 1000 of unity, providing confidence that the chains had converged. The results of our modeling are shown in Table 2. The “Derived Parame-

ters” listed in Table 2 are computed during the sampling as Deterministic parameters in PyMC3.

The best-fitting transit model for the three planets is shown in Figure 6, along with the $1\text{-}\sigma$ bounds of the transit model shown in the space of the data and binned TESS observations. The radii of the three planets are 1.01 ± 0.09 , 2.63 ± 0.4 , and $1.19 \pm 0.11 R_{\oplus}$ from inner to outer planet. TOI-700 b and d are in the Earth-sized regime while TOI-700 c is likely a sub-Neptune-type planet (Rogers 2015). TOI-700 d receives an incident flux of 0.86 ± 0.2 that of Earth’s insolation, which places it within the circumstellar habitable zone (Kopparapu et al. 2013).

To verify the results of our first TESS light curve model, we repeated this analysis but rather than starting with TESS pipeline generated light curves, we began by using the 2-minute cadence target pixel file (TPF) data products (Jenkins et al. 2016). For each of the 11 TPFs, we manually excluded data with significant stray light. Next, we generated custom apertures for each sector by iteratively adding pixels to the aperture ordered by brightness and then selecting the aperture which minimizes the scatter in the light curve. We then use these apertures to generate light curves for each sector. The light curves were extracted using the `lightkurve` package. We then masked out transits using the ephemeris generated by the TESS pipeline alerts and subsequently detrended the light curves using pixel-level decorrelation, adapted from the methods of `everest` (Luger et al. 2016). Once detrended, we combined all 11 sectors into a single light curve. We then used the `exoplanet` package in a similar manner to that described above, except that we used the entire time series as a single dataset rather than breaking it into 11 separate datasets. The resulting exoplanet parameters were consistent at the $<0.2\sigma$ level with the values calculated in our first analysis (see Table 2).

5. SYSTEM VALIDATION OF TOI-700

In Section 4, we modeled the data assuming the signals are caused by planets transiting TOI-700. There are, however, multiple astrophysical false-positive scenarios that can mimic exoplanets that must be ruled out. Several tests are performed in the TESS pipeline in the Data Validation module (DV, Twicken et al. 2018; Li et al. 2019) to search for evidence of false positives in the TESS data. All three planets passed all of DV’s diagnostic tests in the multi-sector search of Sectors 1–13, including the odd/even depth test, the statistical bootstrap test (this tests estimates the probability of a false alarm from random noise fluctuations in the light curve and accounts for the non-white nature of the observa-

Figure 6. Phase-folded, light curve from 11 sectors of TESS data for planets TOI-700 b (upper panel), TOI-700 c (middle panel), and TOI-700 d (lower panel), along with the respective transit model (pink) showing the 1-sigma range in models consistent with the observed data. The corresponding transit parameters are listed in Table 2.

tion noise), the ghost diagnostic test (which compares the detection statistic of the optimal aperture against that of a halo with a 1 pixel buffer “ring” around the optimal aperture – this test can identify when transit-like signatures are caused by background scattered light, background eclipsing binaries and background objects such as asteroids), and the difference image centroiding test.

Here we build upon the pipeline analysis and present validation of TOI-700 b, c, and d. We investigated this system using both observational constraints (Section 5.1) as well as using documented software packages (Section 5.2) to validate the planetary nature of the signals seen by TESS.

5.1. Observational Constraints

We collected a variety of ground-based observations in order to explore potential false-positive scenarios for the TOI-700 system. The majority of these observational constraints were obtained through the TESS Follow-up Observers Program (TFOP). We utilized archival imaging to place limits on background sources (Section 5.1.1), high-resolution speckle imaging to rule out close-in bound companions (Section 5.1.2), high-resolution spectra to place constraints on potential blended sources at even smaller separations (Section 5.1.3), and ground-based time series photometry to observe additional planet transits and rule out nearby eclipsing binaries (Section 5.1.4).

5.1.1. Archival Imaging

TOI-700 was observed three times in historical large-scale photographic sky surveys (Morgan et al. 1992) during epochs spanning 1982 to 1996. These Southern Hemisphere observations were obtained using the UK 1.2 m Schmidt Telescope at Siding Spring Observatory and were made available for digital download as part of the Digitized Sky Survey⁷ (Lasker et al. 1990; Lasker 1994, shown in Figure 7). TOI-700 was observed on 1982 November 20 during the Science and Engineering Research Council (SERC) J survey using the “Blue” photographic emulsion ($\lambda = 395\text{-}590$ nm; Monet et al. 2003) and 1989 December 18 during the SERC-I survey using the “IR” photographic emulsion ($\lambda = 715\text{-}900$ nm; Monet et al. 2003). The star was observed again on 1996 February 19 during the Anglo Australian Observatory Second Epoch Survey (AAO-SES or AAO-R) using the “Red” photographic emulsion ($\lambda = 590\text{-}690$ nm; Monet et al. 2003). The relatively large proper motion of TOI-

⁷ https://archive.stsci.edu/cgi-bin/dss_form

700 allows us to search for background objects at its current position.

With a total proper motion of $191.673 \text{ mas year}^{-1}$, the star has moved approximately $7''$ across the sky to its current location since the SERC-J images were obtained in late 1982. In the archival data, there are no background sources at the star’s current position down to ≈ 17 mag in the SERC-J “Blue” band as shown in Figure 7. We also note there are several faint stars within a separation of $\sim 1'$ of TOI-700 that are within the apertures used to extract the TESS photometry. We compared their photometry in the SERC-I “IR” band, the closest available to the TESS bandpass, with TOI-700 as calibrated and presented in the USNO-B1.0 catalog (Monet et al. 2003). The brightest star is about 7.5 magnitudes fainter than TOI-700 and we find that none of these stars are bright enough to mimic the transits even if they are totally eclipsing binaries. This is consistent with our ground-based time-series observations that rule out nearby eclipsing binaries at the periods of the TOI-700 planets (see Section 5.1.4).

5.1.2. High-Resolution Imaging

If a star hosting a planet candidate has a close bound companion (or companions), the companion can create a false-positive exoplanet detection if it is an eclipsing binary. Additionally, flux from the additional source(s) can lead to an underestimated planetary radius if not accounted for in the transit model (Ciardi et al. 2015; Furlan et al. 2017; Matson et al. 2018). To search for close-in bound companions unresolved in our other follow-up observations, we obtained speckle imaging observations from both Gemini-South’s Zorro instrument and the SOAR HRCam. These observations were obtained through the TFOP.

TOI-700 was observed on 2019 October 08 UT using the Zorro speckle instrument on Gemini-South. Zorro provides simultaneous speckle imaging in two bands (562 nm and 832 nm) with output data products including a reconstructed image and robust contrast limits on companion detections (Howell et al. 2011, 2016). The night had light cirrus, a slight breeze, and very good seeing ($\sim 0.4\text{--}0.5''$) during the observations. Figure 8 shows our 832 nm contrast curve result and our reconstructed speckle image. We find that TOI-700 is a single star with no companion brighter than about 5 to 8 magnitudes, respectively, from the diffraction limit out to $1.75''$. We adopt the Zorro 832 nm band as approximately equal to the *I*-band and estimate that for TOI-700 these limits correspond to an $I \sim 16$ mag star at 0.53 AU and $I \sim 19$ mag star at 54.4 AU.

We also searched for previously unknown companions to TOI-700 with the SOAR speckle imaging camera (HRCam Tokovinin 2018). Data were taken on 2019 October 16 UT in *I*-band, a similar visible bandpass to TESS. We detected no nearby stars within $3''$ (or 93 AU) of TOI-700. The 5σ detection sensitivity and the speckle auto-correlation function from the SOAR observation are plotted in Figure 9.

We also checked for indications of binarity using the Renormalised Unit Weight Error (RUWE) which is calculated for each source in the *Gaia* DR2 catalog. Ziegler et al. (2019) showed that this measure of fit quality was typically < 1.4 for single stars. For TOI-700, $\text{RUWE} = 1.08$, indicating it is comfortably in the single star regime and providing independent verification of the results from the speckle imaging observations.

5.1.3. High-Resolution Spectroscopy

As part of our TFOP reconnaissance spectroscopy campaign to investigate the activity of the host star and rule out close companions unresolved by speckle imaging, we observed TOI-700 on 2019 October 01 UT using the CTIO high-resolution (CHIRON) spectrograph (Tokovinin et al. 2013) in slicer mode on the Cerro Tololo Inter-American Observatory (CTIO) Small and Moderate Aperture Research Telescope System (SMARTS) 1.5 m telescope. CHIRON covers a wavelength range of 410–870 nm and has a resolving power $R = 79,000$. We obtained three 1200 second exposures, which were then median combined to yield a signal-to-noise ratio per spectral resolution element of roughly 28 at 711.59 nm. Using the TiO molecular bands at 706.5–716.5 nm and an observed template of Barnard’s Star, we calculate a radial velocity of $-4.4 \pm 0.1 \text{ km s}^{-1}$.⁸ More details on the analysis are described in Winters et al. (2018). We note negligible rotational broadening ($v \sin i < 1.9 \text{ km s}^{-1}$) and do not see $\text{H}\alpha$ in emission, indicating that the star is inactive. Our analysis of the spectrum reveals no evidence of doubled lines that could originate from unresolved, very close-in, stellar companions.

We ran a series of injection and recovery tests to determine how sensitive we are to any remaining unresolved stellar companions. Under the assumption that any bound (M dwarf) companion will have a line profile similar to TOI-700—modulated only by its intensity and rotation—we used the observed least-squares deconvolution profile of TOI-700 as a template. We injected secondary least-squares deconvolution peaks represent-

⁸ We note that the total uncertainty on the systemic velocity should include the 0.5 km s^{-1} uncertainty on the Barnard’s Star template velocity.

Figure 7. Archival images of TOI-700 from the Digitized Sky Survey showing the location of TOI-700 during the TESS observations (red cross). The star has moved approximately $7''$ since the earliest image in 1982. There are no sources visible at its current location down to a limit of ≈ 17 mag in the SERC-J “Blue” band. The faint stars within $\approx 1'$ are ≥ 7.5 mag fainter than TOI-700 in the SERC-I “IR” band (the closest available to the TESS bandpass) and do not contribute significant flux to the dilute the planet transits.

Figure 8. Gemini-South Zorro speckle observations of TOI-700 taken at 832 nm and the corresponding contrast curve. Our simultaneous 562 nm observation provides a similar result. The red line fit and blue points in the contrast curve represent the 5σ fit to the background sky level (black points) revealing that no companion star is detected from the diffraction limit (17 mas) out to $1.75''$ within a Δ mag of 5 to 8. The reconstructed speckle image (inset) has North up and East to the left and is $2.5''$ across.

ing companions with properties drawn from grids of flux ratios between 1% and 50%, radial velocity separations between -100 and 100 km/s, and rotational velocities between 0 and 10 km/s. For each injection, we re-fit the central line profile with a Gaussian and removed it, and performed a search for a second peak in the residuals. We calculated the significance of the best-fitting Gaussian in the residuals, which we plot in Figure 10. We adopt a 5σ detection threshold due to the possible additional systematic uncertainty introduced by a mismatch

Figure 9. SOAR HRCam *I*-band contrast curve and auto-correlation function (inset). The 2-dimensional autocorrelation function is indicative of a single star. The contrast curve shows that TOI-700 hosts no close companions brighter than $\Delta I \approx 5$ mag at separations beyond $0'.3$.

between the line profiles of primary and secondary components.

We conclude that for radial velocity separations >4 km/s, we can rule out all bound companions with flux ratios greater than about 10%. Given the wavelength range of the CHIRON data used in these analyses, this corresponds to companions with $\Delta R \approx 2.5$ mag. Components with velocity separations <4 km/s are blended with the primary peak and difficult to identify. Chance alignments of background stars with different spectral types can also be detected by this analysis, but may suffer from significant template mismatch, and the significance of their detection would therefore tend to be overestimated. For this reason, we limit our quantitative

Figure 10. Here we show the detection limits for faint companions in the CHIRON spectrum demonstrating that we can rule out the presence of any companion with a flux ratio greater than 10% and an RV separation of >4 km/s.

conclusions to hypothetical bound stellar companions of TOI-700.

We also placed TOI-700 on an observational Hertzsprung-Russell Diagram and compared it to the 1120 M dwarf primaries within 25 pc, as presented in Winters et al. (2019a). The system is not elevated above the main sequence or among the blended photometry binary sequence, which provides confidence that there are no luminous companions to TOI-700, thus validating the results of our high-resolution imaging and spectroscopy.

5.1.4. Time-Series Photometry

We conducted ground-based transit observations of the planet candidates associated with TOI-700 through TFOP. To schedule the observations we used the TESS Transit Finder, which is a customized version of the Tapir software package (Jensen 2013). These measurements aimed to re-detect the transits of the candidates and rule out nearby eclipsing binary contaminants at the relevant periods. The ground based photometric light curves were extracted and analyzed using the AstroImageJ (AIJ) software package (Collins et al. 2017).

TOI-700 b was observed on 2019 December 02 UT at the Siding Spring Observatory (SSO) using both the Las Cumbres Observatory Global Telescope (LCOGT) network (Brown et al. 2013) 1.0-m telescope and the 0.43-m iTelescope T17.⁹ The LCOGT time series was obtained in the z_s -band¹⁰ using exposure times of 50 seconds spanning the event ingress and a partial tran-

sit. The images were calibrated by the standard LCOGT BANZAI pipeline. The iTelescope T17 photometric series was obtained using an FLI ProLine E2V CCD in the *Clear* filter with exposure times of 120 seconds. We checked the field for nearby eclipsing binaries at the period of the planet candidate using custom AIJ scripts. No transit was definitively detected in either time series, but these observations did allow us to rule out nearby eclipsing binaries (within $2.5'$) at the period of TOI-700 b.

TOI-700 c was observed on 2019 November 01 UT at the South African Astronomical Observatory (SAAO) location of the LCOGT. Using the 1.0 m telescope in the z_s -band, observations spanning the full transit plus ~ 1 hour on either side of the transit were obtained with 30 second exposures. We selected an optimal photometric aperture radius of $5.8''$ and an optimal set of seven comparison stars to perform the differential photometry which minimized the 5-minute binned target star model residuals to 0.9 ppt. The planet transit was clearly detected with a transit depth consistent with the TESS data in apertures as small as $2.3''$. The field was also cleared of nearby eclipsing binaries out to $2.5'$ and within $\pm 4\sigma$ of the SPOC transit ephemeris. Joint transit modeling that includes this ground based transit and yields refined parameters of TOI-700 c are presented by Rodriguez et al. submitted.

We attempted two additional ground based observations of TOI-700 c on 2019 August 13, but suffered due to weather and instrumental issues. These included an observation with the SSO LCOGT 1.0 m in z_s -band, and an observation on with the SSO iTelescope T17 in the *Clear* filter. The resulting light curves were insufficient to recover the transit but were used to independently clear the field of nearby eclipsing binaries at the period of TOI-700 c.

TOI-700 d was observed on 2019 November 29 using the SSO 0.43 m iTelescope T17. The time series was collected and analyzed using the same settings and methods as described for TOI-700 b. These observations covered a partial transit plus egress, but were hindered by high clouds. No transit was detected and the quality of the data was only sufficient to partially clear nearby eclipsing binaries at the period of TOI-700 d.

5.2. Software Analysis

As the last step in our vetting and validation process, we used several software packages to further rule out sources of contamination and statistically analyze the likelihood of false-positive signals. We used the DAVE software package, as described in Section 5.2.1, and vespa in Section 5.2.2.

⁹ <https://www.itelescope.net>, <https://support.itelescope.net/support/solutions/articles/231915-telescope-17>

¹⁰ The z_s or z -short filter is similar to a z -band filter but with a cutoff at 920 nm.

Figure 11. An example of a DAVE photometer analysis. This shows Sector 9 data for TOI-700 c. The individual panels show the difference (upper left), out-of-transit (upper right) and in-transit images (lower left), as well as the SNR of the difference image (lower right). There is no significant photometer shift during the two transits observed in Sector 9 in the image shown. No photometer shift is seen for any of the three planets.

5.2.1. DAVE Vetting of the TOI-700 System

DAVE (Discovery and Vetting of Exoplanets) is an automated pipeline built upon vetting tools developed for *Kepler* data (Coughlin et al. 2014a, e.g. RoboVetter), and has been extensively used both for *K2* (Hedges et al. 2019; Kostov et al. 2019a,b) and TESS data (Crossfield et al. 2019; Kostov et al. 2019b). DAVE performs two sets of vetting tests – light curve-based (i.e. odd-even difference between consecutive transits, secondary eclipses, light curve modulations introducing transit-like signals) and image-based (i.e. photometer motion during transit). Our analysis confirms that TOI-700 is the source of the transits of all three planets, and rules out false-positive features such as odd-even differences or secondary eclipses.

Figure 11 shows an example from the photometer analysis of TOI-700 c for Sector 9. Our results are fully consistent with the vetting done as part of the SPOC Data Validation analysis (Jenkins et al. 2016).

5.2.2. vespa Validation of the TOI-700 System

We used *vespa* (Morton 2015) to calculate the false-positive probabilities for the transit signals in the TOI-700 data. *vespa* compares transit signals to a number of false-positive scenarios including an unblended eclipsing binary (EB), a blended background EB, a hierarchical companion EB, and the ‘double-period’ EB scenario. Following the prescription described in Schlieder et al.

(2016), we ran *vespa* using the TESS light curves to calculate the false-positive probability independently for each planetary signal. We included observational constraints in our analysis with the addition of the Zorro 832 nm contrast curve (see Section 5.1.2) as well as the radial velocity constraints derived from the CHIRON data (see Section 5.1.3). We also included a constraint on the maximum depth of potential secondary eclipses associated with each candidate. These constraints were estimated from our DAVE analysis. We ran *vespa* within a $21''$ radius of TOI-700, emulating the size of a TESS pixel. Using these inputs, we calculated the false-positive probabilities to be 0.0012, 0.000086, and 0.0019 for planets b, c, and d, respectively. Given our extensive follow-up and the resulting constraints, the only false-positive scenario with any remaining probability was for the case of a background eclipsing binary, but the probability was $\ll 1\%$ for each planet and is highly disfavored over the true planet scenario. This is consistent with the constraints on background contaminants imposed by our analyses of archival and new ground-based follow-up described previously in this section.

With *vespa* strongly disfavoring astrophysical false positives we can statistically validate the planetary nature of the transit signals. Moreover, *vespa* analysis does not account for any increase in our confidence in a planet scenario based on TOI-700 being a multiplanet system. If we assume that false positives are randomly distributed among stars, then a star with at least one transiting planet is more likely to have a second transiting planet than a false positive (Lissauer et al. 2012). For *Kepler*, this ‘multiplicity boost’ provided approximately a factor of 50 increase in the probability that a planet candidate was a true planet rather than a false positive (Rowe et al. 2014; Lissauer et al. 2014). For TESS, that number has been estimated to be 30–60 for small planets like those in the TOI-700 system (Guerrero et al. in preparation). With this in mind, the probability that any of the TOI-700 planet signals is the result of an astrophysical false positive is highly unlikely.

However, we note that *vespa* does not however take into account potential contamination from instrumental false alarms. Burke et al. (2019) used planet candidates and false positives from *Kepler* Data Release 25 (Thompson et al. 2018) to estimate the instrumental false alarm rate as a function of multiple event statistics (MES, Jenkins et al. 2002) for *Kepler* data. They recommended a typical threshold for long period planets of $\text{MES} > 9$ to avoid false alarms. All three planets orbiting TOI-700 have MES statistics above 9. If TOI-700 d were a single *Kepler* planet, the Burke et al. (2019) estimate of false alarm probability would be 0.18%, although given

TOI-700 d is in a multiplanet system, the [Burke et al. \(2019\)](#) estimate falls to 0.013% false alarm probability. For TOI-700 b and c these false alarm probability values are vanishing small ($\ll 0.1\%$).

While the instrumental false alarm rate for TESS has not been estimated, TESS detectors have fewer image artifacts than *Kepler's* ([Coughlin et al. 2014b](#); [Krishnamurthy et al. 2019](#); [Vanderspek et al. 2018](#)), albeit the pointing performance of TESS is less precise than *Kepler's* and there are background scattered light features in TESS data that were absent from *Kepler*. If we assume that the TESS instrumental false alarm rate is similar to that seen with the quieter detectors in the *Kepler* focal plane array, the false alarm rate for even TOI-700 d falls to $\ll 1\%$. Therefore, under the assumption that the TESS false alarm rate is similar or better than *Kepler's*, the TOI-700 planets are unlikely to be instrumental false alarms. However, this analysis does not independently confirm the planetary nature of the three planets around TOI-700 because *confirmation* of these planets requires detection of a consistent signal with a facility other than TESS. TOI-700 d is a particularly high-interest planet given its size and insolation flux. It is likely to receive a significant amount of follow-up observations from a number of facilities. With this in mind, our group requested, and was awarded, *Spitzer* 4.5 μm observations to independently confirm a transit of TOI-700 d. We describe these observations and a joint analysis of the TESS and other transit data for each planet in the system in Paper II in this series ([Rodríguez et al. submitted](#)).

6. GRAVITATIONAL DYNAMICS

Multiplanet systems provide a rich dataset that can help reveal information that cannot be obtained from single planet systems. Lacking radial velocity measurements needed to obtain mass measurements, herein we use mass-radius relations to estimate the mass values in order to perform a dynamical stability analysis of the planetary system as shown in Section 6.1. We then present a photodynamics and transit timing variation (TTV) analysis in Section 6.2 to determine whether we can place mass constraints from the photometry. Finally we conclude with a search for additional planets in the system in Section 6.3.

6.1. Stability of the Planetary System

Using the planet radii we reported in Table 2, we estimated mass values for each planet using *Forecaster* ([Chen & Kipping 2017](#)) to be $1.07^{+0.80}_{-0.43}$, $7.48^{+5.89}_{-3.30}$, and $1.72^{+1.29}_{-0.63} M_{\oplus}$ for planets b, c, and d, respectively. We used these mass values to perform a suite of numerical

integrations designed to investigate TOI-700's long term dynamical stability over 1 billion orbits of the outermost planet (note that we choose such long integrations given the lengthy timescales for secular resonance overlaps to develop [Lithwick & Wu 2011](#)). The *Forecaster* mass value for TOI-700 c is much higher than the value we constrain using a photodynamic model (see 6.2 and 4), but we explore a range of masses that encompass both in this stability analysis.

Our simulations use the *Mercury6* hybrid integrator ([Chambers 1999](#)) and a 10 hour time-step. We selected initial orbits for each planet using the determined nominal semi-major axes and inclinations, and assumed nearly circular initial eccentricities ($e < 0.001$). To account for the substantial degeneracy in planet masses given the wide range of possible densities, each simulation varies the respective planets' masses such that the entire density range between 1.0 and 12.0 g cm^{-3} is probed. Note that this range includes the lower density constraints for planet c that are discussed in the following section. In order to briefly investigate the possible existence of external, massive planets, we place an additional Neptune-mass planet at 1.0 AU, on a circular orbit, in half of our simulations. We find that, in each integration, eccentricity variations for all planets are smaller than 0.007 (Figure 12). While the moderate inclination of the second planet relative to the other two does drive secular inclination variations within the system (as large as $\sim 1.8^\circ$ for the inner planet in some simulations), this behavior is regular and non-chaotic in all of our integrations. We also check each system for the presence of mean motion resonances and find the planets to be non-resonant within our tested parameter space.

6.2. Photodynamics and Transit Timing Variations

The ratio of mean orbital periods of TOI-700 b and TOI-700 c ($P_c/P_b=1.609$) as observed by TESS is within 1% of the 8:5 orbital resonance. While this is a weak resonance, this observation motivated a photodynamical analysis to attempt a measurement of the mass of the planets in the system. A photodynamical model can assess the potential for mass measurements from mutual gravitational perturbations of the planetary orbits by combining a transit model with an orbital integrator (e.g. [Carter et al. 2012](#)). Gravitational interactions between planets will drive orbital eccentricity to larger values. Thus, constraints on the mean stellar density, ρ_* , as derived in Section 3, together with a photodynamical model can, at minimum, place upper limits on the planetary masses.

Figure 12. The dynamical evolution of the three planets in TOI-700 was simulated to explore long-term stability of the system. The variations in eccentricity (upper panel) and inclinations (lower panel) are shown here for one sample simulation, illustrating that the system is stable on long timescales.

Our photodynamical model used positions for each TESS observation calculated using the *Mercury6* hybrid integrator (Chambers 1999). We then used these positions in the *TRANSITFIT5* transit modeling software (Rowe et al. 2015; Rowe 2016) to calculate transit photometry of the planetary system. We parameterized the photodynamical model with four global parameters: mean stellar density, ρ_* , quadratic limb-darkening, q_1 , q_2 parameterized by Kipping (2013a), and a factor to scale the photometric uncertainty reported for TESS photometry, d_{scale} . For each planet we used seven parameters: the center of transit time, T_0 , defined as when the projected separation between the star and planet as seen by the observer is minimized, the mean orbital period (P_{mean}) as observed by TESS, the impact parameter, b_{T_0} , observed at T_0 , the scaled planetary radius, R_p/R_* , the scaled planetary mass, M_p/M_* and orbital eccentricity parameterized by $\sqrt{e}\cos\omega$ and $\sqrt{e}\sin\omega$.

We matched the photodynamical model to TESS photometry using an MCMC analysis. The MCMC rou-

tine used an affine-invariant ensemble sampler with 480 walkers (Foreman-Mackey et al. 2013). We initialized walkers to sample a wide range of orbital eccentricity and planetary mass to avoid clustering of walkers near a single local minimum. We required initial parameters to be dynamically stable for the duration of the TESS observations. Models were considered to be dynamically unstable if any planet pair came within 3 Hill radii. We adopted a prior on the mean stellar density of $\rho_* = 8.0 \pm 1.8 \text{ g/cm}^3$, as reported in Table 1. We also required masses, radii, and impact parameters to be positive. Orbital inclination is not well constrained by the dynamical portion of photodynamics and negative impact parameters were found to be completely degenerate with positive values in our model. A Markov-chain with a length of 7.68 million was generated. The final 1.68 million entries were examined using the Gelman-Rubin diagnostic (Gelman & Rubin 1992) to assess convergence and adopted to calculate posterior distributions for each model parameter.

Table 3 presents adopted photodynamical model parameters based on our MCMC analysis and includes the mode and 68.27% interval centered on the mode. The mode and interval for each parameter were calculated using a Kernel Density Estimator from *scipy* (Oliphant 2007). In Figure 13, we compare the transit timing predictions from our photodynamical analysis (green lines) with TTVs measured using a best-fit transit model template from *TRANSITFIT5* (black dots with 1σ uncertainty). The photodynamical model was not fit to the template extracted TTVs displayed in Figure 13, but was fit directly to TESS photometry.

Using stellar parameters reported in Table 1 the posterior distribution in the planet mass (M_p), planetary radius (R_p) and planet density (ρ_p) are provided in Table 4. The results show that TTVs for TOI-700 b and c are allowed with potential changes in the orbital period of a few minutes per orbit and provide constraints on the mass and density of the planets. The density of TOI-700 c is fairly well constrained with a 1σ upper limit of 1.9 g/cm^3 . This limit requires TOI-700 c potentially have a significant H/He envelope with a density that is significantly lower than what would be expected for a rocky planet. The orbit of TOI-700 d was not found to be strongly perturbed by TOI-700 b or TOI-700 c in our analysis on the timescale of TESS observations. However, additional transit timing measurements of the TOI-700 system are needed to reach strong conclusions for planets b and c as the models diverge very quickly.

6.3. Search for Additional Planets

Figure 13. The Observed minus Calculated (O-C) transit times for TOI-700 b, c, and d are presented; comparing measured transit times (black markers) and photodynamical times (green lines). For each TESS transit, the Observed transit time from photodynamics is compared to the Calculated transit time based on the modelled mean orbital period and displayed as green lines. There are 2000 green lines that present models randomly sampled from MCMC analysis of TESS photometry with our photodynamical model. Thus, the density of the lines indicated the probability of deviations from a strictly periodic orbit. The black markers are measured transit times based on a template analysis of TESS photometry and are presented to visualize the expected timing for each observed transit. The green lines are not fit to the black timing measurements but represent the range of TTVs allowed by TESS photometry which can be visually compared to timing measurements of each individual transit.

To complement and reinforce the SPOC pipeline planet detections, we ran our own independent planet search on the light curve. Using QATS (Quasi-periodic Automated Transit Search, Kruse et al. 2019), we recovered the three planet candidates but found no evidence for further transiting planets in the system; the QATS search also allowed for planets exhibiting TTVs, but no additional candidates hidden by strong TTVs were found.

7. DISCUSSION

Table 3. Photodynamic Model Parameters

Parameter	Mode	+1 σ	-1 σ
ρ_* (g cm $^{-3}$)	8.1	+1.9	-1.0

TOI-700 is an exciting three-planet system orbiting a nearby M dwarf star. In this section we aim to put TOI-700 into context with other planetary systems, and

consider the value of this system for habitability and atmospheric studies and the prospects for future follow-up characterization.

7.1. Comparison to other Multiplanet Systems

The TOI-700 planetary system consists of three planets, with two approximately Earth-sized planets and a larger planet (2.6 times the size of Earth) orbiting in-between. This architecture is unusual compared to other multiplanet systems with small habitable zone planets (Figure 14). Studies of the *Kepler* multiplanet population have found that planets within a given multiplanet system tend to have similar sizes, regular orbital spacings, and circular and coplanar orbits (if measurable) (Millholland et al. 2017; Weiss et al. 2018). The TOI-700 system architecture breaks this trend.

Planetary embryos growing by accreting planetesimals tend to end up at similar sizes (Lissauer 1987; Kokubo & Ida 1998). This is also true for pebble accretion (Lambrechts & Johansen 2014; Ormel et al. 2017). While one might expect gas accretion to proceed at a similar rate for neighboring planets (Ikoma et al. 2001; Millholland et al. 2017), small differences in the planets’ formation times or the local gas opacity could easily change this.

What formation scenarios might explain the origin of a system like TOI-700 containing a low-density planet bracketed on either side by higher-density planets with similar masses? Perhaps the two inner planets formed faster and accreted significant gaseous envelopes but the outer planet formed more slowly and accreted less gas. Photo-evaporation is extremely sensitive to the orbital separation (Lopez & Fortney 2013), so the inner planet may later have lost its envelope. Alternately, long-range orbital migration causes large diversity in planetary feeding zones, and therefore, compositions (Raymond et al. 2018). One could imagine that planet c migrated inward from the outer parts of the disk and thus formed under different conditions (and perhaps faster) than planets b and d. However, given the apparent similarities in their masses (see Table 4) it is hard to understand why one planet would have migrated inward but not the others. This second scenario would become more plausible if future studies indicate that the mass of planet c is significantly larger than that of planets b and d.

The sizes of the planets orbiting TOI-700 span the observed gap in the transiting planet radius distribution (Fulton et al. 2017; Van Eylen et al. 2018; Cloutier & Menou 2019). The inner and outer planets are likely to be rocky, whereas the middle planet likely has a gaseous envelope and is more akin to Neptune (Rogers 2015; Lopez & Fortney 2014). This system is therefore a great

Figure 14. A top-down view of the orbits of the TOI-700 planets (upper panel). The relative sizes of the planets are to scale, but are not on the same scale as the orbits. The conservative habitable zone is shown in dark gray, and the optimistic habitable zone in light gray (Kopparapu et al. 2013). We also compare the TOI-700 system to the Solar System and other benchmark exoplanet systems with small habitable-zone planets (lower panel).

laboratory to explore the formation mechanisms of compact multi-planet systems and for future atmospheric studies.

7.2. Atmospheric Stability

One of the key questions for the exoplanet community is, “under what conditions are rocky exoplanets able to retain an atmosphere?” Recent observations of thermal emission from the rocky exoplanet LHS 3844 b indicate that it is likely airless (Kreidberg et al. 2019). Furthermore, a large and growing body of literature indicates that most of the rocky exoplanets found by *Kepler* have likely been heavily sculpted by extreme atmospheric escape (e.g., Lopez et al. 2012; Owen & Wu 2013, 2017; Lopez 2017; Zahnle & Catling 2017; McDonald et al.

2019; Neil & Rogers 2019). This is a particular concern for planets around M dwarfs, where the host stars' long pre-main sequence lifetimes and frequently high activity levels mean that even rocky planets with heavier secondary atmospheres in or near the habitable zone are highly vulnerable to extreme atmospheric escape driven by space weather in the form of ionizing radiation (x-ray and Extreme UV [XUV], 1-1240 Å) and stellar wind particles (e.g., Lissauer 2007; Lammer et al. 2007; Cohen et al. 2014; Owen & Mohanty 2016; Bolmont et al. 2017; Garcia-Sage et al. 2017; Dong et al. 2017; Garraffo et al. 2017; Cohen et al. 2018; Airapetian et al. 2019).

In this context, the TOI-700 system presents an exceptional opportunity since it contains three planets well-suited to detailed characterization around a bright, nearby M dwarf with low levels of stellar activity. As discussed in Section 3.4, over the 11 sectors observed with TESS we do not observe a single white-light flare, and its slow rotation rate of 54 days places it firmly into the low-activity sample of M dwarfs identified by Newton et al. (2017). Stars with rotation rates this slow are observed to have low x-ray luminosities with $L_X/L_{\text{bol}} \approx 10^{-5}$ (e.g. Kiraga & Stepien 2007), whereas more active M dwarfs like Proxima Centauri and TRAPPIST-1 have L_X/L_{bol} in the range of $\approx 2 \times 10^{-4} - 10^{-3}$ (Wheatley et al. 2017). TOI-700 has not been studied at x-ray wavelengths, but we can use the star's rotation period of 54 days to constrain the x-ray luminosity for the star to $L_x \leq 2.4 \times 10^{27}$ erg, which is comparable to the X-ray luminosity of the Sun at solar maximum (Aschwanden 1994; Peres et al. 2000). This lower x-ray luminosity is critically important to atmospheric survival as it also strongly correlates with other key drivers of atmospheric escape including EUV irradiation and stellar wind particle flux (e.g., Lammer et al. 2003; Owen & Jackson 2012; Khodachenko et al. 2007; Cohen et al. 2015; Airapetian et al. 2017; Dong et al. 2018).

TOI-700 d is of particular interest as a likely rocky planet in the habitable zone. An empirical relationship between EUV and x-ray fluxes for G, K, and early M dwarfs (Sanz-Forcada et al. 2011) implies a total XUV incident flux at TOI-700 d of approximately $65 \text{ ergs s}^{-1} \text{ cm}^{-2}$, approximately 35 times greater than the XUV flux at present-day Earth and 50 times lower than that received by TRAPPIST-1 e (Wheatley et al. 2017).

Much work still needs to be done to understand the processes that drive atmospheric escape from rocky exoplanets. However, to get an initial idea we used an escape rate scaling law for an Earth-like planet, to estimate the possible rate of O^+ and N^+ ion escape (Airapetian et al. 2017). Assuming Earth's surface gravity, atmospheric composition, and magnetic moment,

along with quiescent conditions from the host star, with no observed flares and associated coronal mass ejections, gives a total ion mass loss rate of $1 \times 10^5 \text{ g/s}$. At this escape rate, a planet with a 1 bar Earth-like atmosphere would survive for longer than $\gtrsim 1$ Gyr even if there was no atmospheric replenishment due to volcanic activity. Assuming that the XUV emission at the early phase of the stellar evolution was about 10 times higher, the corresponding escape rate would be comparable to the outgassing rate of $1 \times 10^6 \text{ g/s}$ via volcanic activity on the early Earth-like planet (e.g. Claire 2008; Schaefer & Fegley 2007), suggesting that this planet may have been able to retain an earth-like secondary atmosphere. As a result, along with other recent discoveries of potentially rocky transiting planets like those in the TRAPPIST-1 system, we believe that TOI-700 may present a valuable opportunity to compare the atmospheres of rocky planets in the habitable zone over a wide range of conditions affecting atmospheric escape.

7.3. Prospects for Follow-up

Prior to the launch of *Kepler*, it was unknown whether Earth-sized planets in the habitable zones of other stars existed. Particularly for M dwarfs, the Galaxy's most common type of star, this question has been of great interest due to the implications for the abundance of habitable planets in our galaxy. Of the more than four thousand exoplanets discovered to date, only about a dozen are Earth-sized and reside in their stars' habitable zones. However, we now know that Earth-sized, habitable zone planets orbit stars that span the full range of M dwarf masses: from the ultra-cool M8 dwarf TRAPPIST-1 ($0.08 M_{\odot}$) to the M0 dwarf Kepler-186 ($0.5 M_{\odot}$), and in-between this mass range is the M3 dwarf K2-72 ($0.3 M_{\odot}$). We can now add the M2 dwarf, TOI-700 ($0.42 M_{\odot}$), to this growing list.

For detecting and characterizing planetary atmospheres, TRAPPIST-1 is a prime target since the planet-to-star size ratio is extremely high due to the diminutive size of the star (approximately the size of the planet Jupiter). TRAPPIST-1 also resides at 12 pc and has a *K*-band magnitude of 10.3. TOI-700 also has the small star advantage, but another advantage over *Kepler* and *K2* targets is the star's proximity to observers (31 pc, versus 179 and 70 pc for Kepler-186 and K2-72, respectively), and its *K* magnitude of 8.6. The TRAPPIST-1 and TOI-700 systems provide an opportunity to compare planets within the same system which formed in the same stellar environment to those that formed in very different M dwarf stellar environments. While TRAPPIST-1 and TOI-700 are both M dwarfs, the difference in mass between the two is more than a

factor of four, whereas the masses of TOI-700 and the Sun differ by less than a factor of three. Moreover, TOI-700 is relatively old and quiet, whereas TRAPPIST-1 is fairly active (Vida et al. 2017), providing the opportunity to explore how activity affects atmospheric escape.

Following the methods of Kempton et al. (2018), we took an initial look at the potential for future atmospheric follow-up with JWST by calculating the transmission spectroscopy metric (TSM) of each planet. The TSM for planets TOI-700 b, TOI-700 c, and TOI-700 d are 5.40, 73.64, and 3.49. While a TSM of 3.49 is the highest of any habitable zone planet smaller than $1.5 R_{\oplus}$ not orbiting TRAPPIST-1, it is still relatively low.

To achieve a $\sim 5\sigma$ detection of biosignatures or other molecules in the atmosphere of TOI-700 d would likely require over 100 transits using JWST (See Paper II in the series, Rodriguez et al. submitted). Paper III in this series, Suissa et al. (submitted), provides detailed modeling of plausible atmospheres of TOI-700 d and the resulting detectability using future observing facilities.

TOI-700 c, on the other hand, is a sub-Neptune-sized planet around a bright M-dwarf with a high TSM value, making it an excellent candidate for further investigation. A TSM of 74 is amongst the highest of planets in the ‘Venus Zone’ (Kane et al. 2014), and may provide an excellent opportunity to characterize this sub-Neptune with the Hubble Space Telescope and JWST.

7.3.1. Radial Velocity Follow-up

For radial velocity observations, we estimated the signals needed to constrain the masses of the TOI-700 planets. The three planets in the system, from inner to outer, TOI-700 b, c, and d, have expected Doppler semi-amplitudes of 0.57, 3.4, and 0.59 m/s, respectively, with uncertainties around 20% (using the *Forecaster* mass-radius relation). While the velocity semi-amplitude of planet c is well within the capabilities of current Southern Hemisphere instruments such as HARPS and PFS (Mayor et al. 2003; Teske et al. 2016), the orbital period of TOI-700 c of 16.05 days is close to one-third of the ~ 54 -day stellar-rotation period. The rotational modulation of stellar activity introduces apparent velocity changes of a few m/s for quiet, main sequence dwarfs. The strongest of these changes occur at time-scales equal to one-third, one-half and one times the stellar rotation period for intensely sampled cadences (Vanderburg et al. 2016), and also at other spurious periods both longer and shorter than the rotation period that can persist for multiple observing seasons for less well-sampled cadences (Nava et al. 2019). This will confound the interpretation of the radial velocity signal for all of the TOI-700 planets without novel methods for

Figure 15. There are now 11 known exoplanets that have radii less than $1.5R_{\oplus}$ and orbit within their star’s optimistic habitable zone (Kopparapu et al. 2013). Plotted are these planets’ TSM values. The top candidates for atmospheric characterization orbit TRAPPIST-1. Beyond these, TOI-700 d has the highest TSM, although characterizing this planet will be challenging.

mitigating stellar activity in radial velocities such as recently probed with line-by-line analysis and chromatic radial velocities (Cretignier et al. 2019; Dumusque 2018; Lanza et al. 2019; Tal-Or et al. 2018).

Planets b and d will be challenging because of the relatively low expected amplitudes under 1 m/s, and will require excellent instrument stability. ESPRESSO is currently the only Southern Hemisphere facility with demonstrated instrument single measurement precision of less than 0.5 m/s on sky that can access TOI-700 (Pepe et al. 2014; Faria et al. 2019). TOI-700 provides an excellent benchmark case for ESPRESSO to explore the limits of techniques for stellar activity correction in radial velocity spectra time-series for early M dwarfs with multi-planet systems.

While planet c is well within the capabilities of current instruments, planet b, and particularly d will be challenging because of the relatively long orbital period of the planet and low expected amplitude, and will require excellent instrument stability.

7.3.2. Additional Photometry from TESS’s Extended Mission

The TESS extended mission is scheduled to begin July 4, 2020. TESS will return to the Southern Hemisphere where it will re-observe TOI-700 for 11 of the 13 sectors in TESS Guest Investigator Program Cycle 3. The full-frame image data will be collected at 10-minute ca-

dence in the extended mission, and targets can be proposed for both 2-minute cadence observations and a new 20-second cadence mode. Additional photometry, combined with that presented herein, will allow for better constraints on planet parameters, enable searches for additional planets, and collect more transit time measurements to improve our TTV analysis.

8. CONCLUSIONS

We present the discovery and validation of three small planets ($R_p = 1.01, 2.63, 1.19 R_\oplus$) orbiting TOI-700, a bright, nearby (distance = 31.1 pc) M2 dwarf ($0.416 M_\odot, 0.42 R_\odot$, with a temperature of 3480 K). The outermost planet, TOI-700 d, is approximately Earth-sized and resides in the star’s habitable zone.

After extensive ground-based follow-up observations, we find no evidence of binarity or contamination of the light from the host star. We further vetted the system using the *DAVE* and *vespa* software packages, and showed that the signals in TESS data are planetary in nature and highly unlikely to be false positives.

TOI-700 d affords us the exciting opportunity to study an Earth-sized, habitable zone planet. TOI-700 c is also an excellent target for detailed follow-up. The sizes of the planets in the system constituents span the observed gap in the transiting planet radius distribution, therefore this system is an intriguing target for studies of planet formation and comparative planetology. TOI-700 is a quiet star, with no detectable flares in the optical TESS data, making it an optimal target for habitability studies of planets orbiting M dwarfs.

TESS will return to the Southern Hemisphere observe TOI-700 for an additional 11 sectors in TESS’s extended mission, which is scheduled to begin in July 2020. This will enable studies for additional evidence of transit timing variations, place further constraints on planet parameters, and searches for additional planets in the system.

ACKNOWLEDGMENTS

This paper includes data collected by the TESS mission, which are publicly available from the Mikulski Archive for Space Telescopes (MAST). Funding for the TESS mission is provided by NASA’s Science Mission directorate. We acknowledge the use of public TESS Alert data from pipelines at the TESS Science Office and at the TESS Science Processing Operations Center.

This research has made use of the Exoplanet Follow-up Observation Program website, which is operated by the California Institute of Technology, under contract

with the National Aeronautics and Space Administration under the Exoplanet Exploration Program.

This work has made use of data from the European Space Agency (ESA) mission *Gaia* (<https://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, <https://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement.

Some of the observations in the paper made use of the High-Resolution Imaging instrument Zorro at Gemini-South. Zorro was funded by the NASA Exoplanet Exploration Program and built at the NASA Ames Research Center by Steve B. Howell, Nic Scott, Elliott P. Horch, and Emmett Quigley.

Resources supporting this work were provided by the NASA High-End Computing (HEC) Program through the NASA Advanced Supercomputing (NAS) Division at Ames Research Center for the production of the SPOC data products.

This work makes use of observations from the LCOGT network.

E.A.G. thanks the LSSTC Data Science Fellowship Program, which is funded by LSSTC, NSF Cybertraining Grant #1829740, the Brinson Foundation, and the Moore Foundation; her participation in the program has benefited this work. E.A.G. and E.V.Q. are thankful for support from GSFC Sellers Exoplanet Environments Collaboration (SEEC), which is funded by the NASA Planetary Science Division’s Internal Scientist Funding Model.

J.F.R. acknowledges research funding support from the Canada Research Chairs program and NSERC Discovery Program. This research was enabled, in part, by support provided by Calcul Québec (www.calculquebec.ca) and ComputeCanada (www.computeCanada.ca)

A.V.’s work was performed under contract with the California Institute of Technology (Caltech)/Jet Propulsion Laboratory (JPL) funded by NASA through the Sagan Fellowship Program executed by the NASA Exoplanet Science Institute.
